

Early Journal Content on JSTOR, Free to Anyone in the World

This article is one of nearly 500,000 scholarly works digitized and made freely available to everyone in the world by JSTOR.

Known as the Early Journal Content, this set of works include research articles, news, letters, and other writings published in more than 200 of the oldest leading academic journals. The works date from the mid-seventeenth to the early twentieth centuries.

We encourage people to read and share the Early Journal Content openly and to tell others that this resource exists. People may post this content online or redistribute in any way for non-commercial purposes.

JSTOR is a digital library of academic journals, books, and primary source objects. JSTOR helps people discover, use, and build upon a wide range of content through a powerful research and teaching platform, and preserves this content for future generations. JSTOR is part of ITHAKA, a not-for-profit organization that also includes Ithaka S+R and Portico. For more information about JSTOR, please contact support@jstor.org.

ESSAY *on the* BEST METHOD *of* ASCERTAINING *the*
 AREAS *of* COUNTRIES *of* CONSIDERABLE EXTENT.
By the Rev. JAMES WHITELOW, Vicar of St. Catherine,
Dublin, and M. R. I. A.

MODERN geographers, and particularly those of Germany, have, of late years, cultivated a science to which they have given the name of *Statistics*, the object of which is, to ascertain the extent, population, density of population, military and naval force, revenues, national debt, &c. of the various states of Europe. This science, interesting to every enlightened mind, and peculiarly so to the statesman, is, as yet, in its infancy; and that particular branch of it, which enables us to determine the areas or superficial contents of countries, has been hitherto so neglected, or conducted on such erroneous principles, that the calculations of different authors are perfectly inconsistent with each other, and with truth. Some areas in our tables are, it must be acknowledged, sufficiently accurate; but as truth and error are advanced with equal confidence, and equal authority, such are useless to the reader, who, incompetent to make a selection, cannot proportion his assent to their merit.

Read April
 25, 1795.

THE strange inconsistencies that occur in statistical tables will appear more surprising, when we consider that the present cultivated state of geography, though far from perfection, leaves little room for those enormous errors which were formerly inevitable: When such, therefore, occur in modern publications, we may justly, I think, impute them either to want of skill or want of care in the author; and conclude that his method was incorrect, or that he performed the operation on very erroneous maps. The following are a few of the numerous inconsistencies to which I allude, but sufficient to shew the very imperfect state of this part of the science of statistics.

Europe in square Miles, of 60 to a Degree, by various Authors.

Kitchin's map of Europe, according to				
Zimmermann,	-	-	2,180,466—	Difference between each and Kitchin's map.
Busching	-	-	2,432,000—	
Statistische Ueberficht or German po- litical Tables 1786	-	-	2,712,112—	
Templeman's Survey of the Globe	-	-	2,749,314—	
Crome, on the Size and Population of Europe 1785	-	-	2,785,440—	
Bergman's Natural Geography	-	-	2,906,112—	

Here the last difference is above four times the area of the kingdom of France.

AMIDST

AMIDST errors of such magnitude how can we discover truth ? is an obvious question. It has often employed my thoughts, and I take the liberty of submitting the result to the Academy.

A *small* portion of the earth's spherical surface may be accurately represented by a map drawn on a plain surface, and the mensuration of such map, by the ordinary methods used by surveyors, will give the area of the country it represents, with sufficient correctness : but in maps of extensive regions the rule no longer holds, and the impossibility of justly delineating any considerable portion of a sphere on a plain has induced geographers to have recourse to the various methods of projection, such as the stereographic, orthographic, &c. Maps constructed on such principles may give the relative situation of places, with respect to bearing, meridians and parallels, but cannot convey any accurate idea of form or superficial contents: they are, at best, but distorted resemblances, and the greater the extent they embrace the greater the distortion, and the more incorrect the area: to such maps a scale cannot be applied, and they are consequently totally unfit for the purpose of mensuration.

THAT the area of even a single kingdom of moderate dimensions must differ very considerably from that of its map, will be evident from considering the different methods of constructing the latter.

THE usual kinds of projection for particular maps are the stereographic on the plane of the horizon, the conical, and the circular.

IN the first, which is founded on the rules of perspective, equal tracts of country are represented as very unequal, gradually encreasing as they recede from the centre of the plane of projection; hence no common scale can be applied to the map, which is therefore totally unfit for mensuration.

THE conical projection is so called, as it is produced by the application of a cone to a sphere, according to certain rules. In this the meridians are right lines on the cone, converging at its vertex, and perpendicular to the parallels of the lat. which are circles, described from the vertex as their common centre: The distance between the meridians is correct, only on the two parallels formed by the interfections of the sphere and cone, between which they will approach too near, and every where else recede too far from each other; and hence the area of that part of the map delineated on the portion of the cone which falls within the sphere will be less than the truth, while without those limits it will proportionably exceed it. This is an ingenious and elegant projection, and as the conical area between its extreme meridians and parallels is perfectly equal to that portion of the sphere it represents, if the limits of the country delineated on it perfectly coincided with those lines, it would necessarily give the true area: But this never happens, and to
speak

speaking with mathematical accuracy it is liable to the same objection as the last, viz. that a scale cannot be applied to it; for countries, however, of moderate extent in latitude, it is the best that can be devised.

IN the circular projection the parallels of lat. are circles, described from the pole as the common centre, with radii equal to the complements of their respective latitudes: the meridians preserve their due distances on the parallels, becoming gradually curvilinear, and cutting the parallels more and more obliquely, as they recede from the central meridian; but as this alone cannot be a right line, and cut the parallels perpendicularly, it is obvious, that this projection must produce distortion in the map, and consequently an error in its area, which, if it is greatly extended in longitude, will at length become enormous: for countries, however, of moderate dimensions, it is one of the least objectionable projections, and a scale may be adapted to it with sufficient accuracy, though not with geometrical precision.

THERE is another method of projection, used by the Sansons, in which the parallels are right lines, and the meridians, which observe their due distances on the parallels, are parabolic curves. This is admissible only in delineating countries of inconsiderable extent in longitude, and Mr. D'Anville has preferred it for his map of South America: In all other cases it produces much greater distortion than any of the above methods.

IN

IN the cylindrical projection the countries on each side of the equator are conceived to be delineated on the surface of a cylinder, cutting the sphere in two parallels, nearly midway between the equator and the top and bottom of the map: The meridians and parallels are right-lines, cutting each other at right-angles, and the former observe their due distance only on the interfections of the cylinder and sphere: This projection is evidently the best for the tropical regions; but, as it is not of general application, and partakes of the perfections and imperfections of the conical, it is sufficient to have mentioned it.

ALTHOUGH it is thus evident that the area, resulting from the simple mensuration of every species of map, however projected, must, (except the country represented be of small extent) differ considerably from the true area, yet there is reason, I think, to suspect that the generality of statistical writers have only performed the operation in the usual way, and perhaps on maps injudiciously selected, without taking any precaution to correct the errors which must inevitably arise from such a process; at least the strange inconsistency observable in their tables, with their want of candour, in not communicating to the public their method and materials, subject them to this suspicion. A few, indeed, have given us some numbers sufficiently correct, but by what means they discovered truth, as they are silent on the subject, we are ignorant. I shall, therefore, make no apology for offering the following method of nearly determining the true areas of maps: It is, I believe, new, and will be found, I hope, sufficiently

sufficiently accurate for the purposes for which statistical tables are intended; for minute precision is impossible, and if possible would be unnecessary.

Method of nearly determining the true Areas of Maps on the Conical and Circular Projections.

Parallels of latitude, distant from each other one degree, will divide the spherical surface of the earth into 180 narrow zones; the area of each of these, in square miles of 60 to a degree, is found by multiplying its sine in miles and decimals of a mile by 21600, the circumference of a great circle in such miles; and the area of each zone, thus found, divided by 360, will give the area of each of the quadrilateral spaces, formed by the parallels, which include the zone and two meridians distant one degree of longitude from each other: On this principle the following table was constructed.

Lat.

Lat. of the Zones.	Area of Quadrilat.	Lat. of Zones.	Area of Quadrilat.	Lat. of Zones.	Area of Quad.	Lat. of Zones.	Area of Quad.	Lat. of Zones.	Area of Quad.

To

To render the application of the above table and subsequent process more intelligible, I have annexed a sketch of the projection and outline of the map of Germany.

HAVNIG drawn the contour of the country with all possible accuracy, and expressed it by a very fine line, observe what quadrilateral spaces lie entirely within it; enclose these by a strong black line, and the area of all within it we may call the *integral area*, as it consists of entire quadrilaterals; and that without it, the *fractional area*, as it is composed of parts of quadrilaterals.

THE *integral area* may be found with the greatest accuracy thus: I find, in the table, that a quadrilateral between the 53d and 54th parallel contains 2138.2 square miles, and that there are six such in the *integral area*; therefore $2138.2 \times 6 = 12829.2$ will give the true contents of that portion of it which lies between these parallels, and a similar operation for the zones between the other parallels will give 144023.6 as the entire *integral area* of Germany.

THUS far (supposing the map correct) there is no possibility of error. The contents of the fractional area can be found only by approximation: The method I propose is this:

LET it be required to find the area of the space A in the quadrilateral a b c d: having constructed a scale, from the extent of a degree of latitude, reduce the irregular waving contour a b c

K
into

Fig. 1.

into a rectilineal outline, by short balance, or (as they are vulgarly called) give and take lines, drawn by the assistance of a transparent ruler, with a thin fiducial edge: The polygonal space A must then be reduced to a triangle by an operation familiar to surveyors, and its area found, by the usual mode of multiplying half its altitude into its base: By a similar process, find the area of the polygonal space B, which added to that of A, will give the area of the quadrilateral; and if this nearly coincides with the sum, which results from multiplying its mean extent in longitude by 60, there has been no material error in the operation: The sum of the areas thus found will be frequently very different from the true area of the quadrilateral, shewn by the table, and the error must be corrected by dividing the difference between the true and measured areas proportionally between the spaces A and B, thus,

LET the quadrilateral a b c d be situate between the 50th and 51st parallels of latitude, and its true area of course 2287 square miles: But, in consequence of the inevitable deviation from truth, in the projection of the map, this area produces by mensuration only 2247 square miles; the space A 1032, and the space B 1215: To find the true areas of A and B,

as 2247 the measured area of the quadrilateral.
 : 1032 the measured area of A.
 :: 2287 the true area of the quadrilateral.
 : 1050 the true area of A.

as

as 2247 the measured area of the quadrilateral.
 : 1215 the measured area of B.
 :: 2287 the true area of the quadrilateral.
 : 1237 the true area of B.

WHEN the true extent of the portions into which the contour line divides the quadrilaterals is thus adjusted, the addition of the several numbers in the *fractional area* to the *integral* will give the contents of the map: and to prevent any confusion in the numbers to be added, it will be adviseable to stain the *fractional area* one uniform colour, and to add the numbers in the different zones in separate columns.

By the above rules I measured the annexed map of Germany, including the Austrian Netherlands, taken from Mr. D'Anville: The following table shews the result and its relative proportion to the areas of different authors.

Mr. D'Anville's map taken from his					
first part of Europe, 1754	-	192552			
Templeman's Survey of the Globe	-	156950—35602	—		
Busching, 1780	-	177984—14568	—		
(Statistische Uebersicht) in German,					
1786	-	192000—552	—		
Crome on the Size and Population of					
Europe, 1785	-	204736—12184	+		

Difference between each and D'Anville's map.

If the above method of finding the *fractional area* is not thought sufficiently correct, I would propose the following, more laborious, indeed, but, if properly executed, more accurate.

A QUADRILATERAL, not exceeding one degree in extent, when accurately drawn on a plane surface, will produce an area by careful mensuration differing about 1.3 square miles in 1000 from its true extent on the sphere; this error therefore being immaterial, delineate each quadrilateral in the fractional area on a separate paper, and having drawn the contour line through it with great care and accuracy, measure each part as directed above, and if the sum of the areas resulting from this operation nearly equal that in the table, the operation may be considered as free from material errors; the small difference that arises must be proportionally divided between the parts of the quadrilateral, that the whole and parts may be perfectly consistent, and the numbers thus corrected written in their proper spaces in the map.

Area

[75*]

*Area of Germany and Switzerland, according to the Map of
Mr. D'Anville, measured by the foregoing Method.*
